

TITLE: DEVICE AND METHOD OF OPERATION

The present invention relates to a device, notably a high speed solenoid type valve and to an ink jet printer
5 containing such a valve; and to a method of operating an ink jet print head utilising that valve.

BACKGROUND TO THE INVENTION:

10 Ink jet printers are non-contact printers in which droplets of ink are ejected from one or more nozzles in a print head. The ejected droplets are projected onto a substrate moving relative to the print head and progressively build up a printed image on the substrate
15 from the dots of ink applied to the substrate. For convenience, the present invention will be described in terms of a substrate which moves with respect to a stationary print head. However, the invention may also be applied to printers in which the print head moves with
20 respect to a stationary substrate. The invention can thus be applied to printers in which the substrate and the print head move relative to one another.

One form of ink jet printer comprises a source of ink
25 under pressure, typically a reservoir or bottle of ink which is pressurised to from 0.1 to 3 bar, notably about 1 bar. The pressure is created, for example, by pressurising the air space above the ink in the bottle or reservoir. The ink is fed to a nozzle orifice in a print
30 head through which it is ejected as a series of droplets onto the surface of the substrate. The print head

- 2 -

typically comprises a row of such nozzle orifices arranged transversely to the direction of travel of the substrate. The flow of ink through each nozzle orifice is controlled by a solenoid valve. Typically, such a valve comprises an
5 electromagnetic plunger journaled for axial movement within an axially extending electric coil. The distal end of the plunger is located within a valve head chamber through which ink flows from the reservoir to the nozzle orifice. When current is fed through the coil, this
10 generates a magnetic field which acts on the plunger to move it axially and thus open, or shut, the inlet to a bore or conduit to the nozzle orifice. Typically, the magnetic field acts to retract the plunger against the bias of a coil spring to create a flow path between the
15 valve head chamber and the nozzle orifice. When the electric current no longer flows in the coil, the magnetic field ceases and the plunger returns under the bias of the spring to seat against sealing ribs, lips or other means located at or around the inlet to the bore or conduit to
20 the nozzle orifice so as to close the flow path to the nozzle orifice. Typically, a plurality of nozzle orifices are formed as a row in a plate, the nozzle plate, and each nozzle orifice is served by a bore through the plate connected to a solenoid valve. Typically, the nozzle
25 orifice is provided as the distal end of a bore in a jewel nozzle, which is seated into the outlet end of a bore through the nozzle plate. Droplets of ink are ejected independently from one or more of the nozzle orifices upon actuation of the valve controlling the flow of ink to that
30 nozzle orifice.

- 3 -

The valves are fed with ink from the reservoir via a manifold which serves to split and even the ink flow to each of the valves. The row of nozzle orifices is typically aligned transversely to the direction of travel of the substrate, so that simultaneous operation of the valves will cause a row of ink dots to be printed on the substrate. The valves are operated so as to deposit dots of ink upon the substrate at the desired locations on the substrate to build up the elements of a five, seven, eight or more dot raster image on the substrate. By suitable sequencing of the opening of the various valves serving the nozzles, dots of visible ink can be applied to form an alphanumeric or other image, a production date, product batch code, logo, bar code or other visible image on the substrate. Alternatively, the ink can be one which forms a UV fluorescent or magnetically readable machine readable image which is invisible to the human eye, for example a security or product authentication code. If desired, several nozzle plates can be combined in an array so as to print a wider image on the substrate and/or to achieve close printing of the dots on the substrate by staggering the nozzle plates with respect to one another.

For convenience, the term drop on demand printer will be used to denote in general such types of ink jet printer; the term ink will be used to denote pigmented and dye based inks which form a visible image and other fluid compositions which may not be visible but which are machine reader detectable; the term nozzle orifice will be used to denote the aperture through which the ink droplet is ejected; the term nozzle bore will be used to denote

- 4 -

the bore connecting the valve head chamber with the nozzle orifice; and the term print head will be used to denote an assembly having one or more nozzle orifices and associated valves.

5

For a given nozzle orifice diameter, the size of the printed dot can readily be altered by varying the duration for which the valve is held open, and hence the amount of ink that is allowed to flow through the nozzle orifice for each opening of the valve. The form of the image which is printed can readily be altered by varying the sequence of operation of the valves in the print head so that droplets are ejected from the appropriate nozzles in the appropriate sequence to form the desired image. Such alterations of the images and the dot sizes can readily be controlled by a computer or microprocessor operating under an appropriate program or operating system.

Such drop on demand printers are widely available commercially and find widespread use in printing a wide range of both visible and non-visible machine-readable images on a wide range of substrates. Since the ink is ejected from the nozzle orifice at a pressure of from 1 to 5 Bar, the print heads can project the droplets from the nozzle orifices for a flight path length of 10 to 25 mms or more. This allows the print head to be located adjacent to a line of travelling articles in a production or packaging line, without the print head fouling the articles.

30

However, as the relative speed of travel between the print

- 5 -

head and the substrate increases, a point is reached at which the valve cannot be operated at sufficient speed to eject droplets at sufficient frequency to form the desired image without creating some distortion. Typically, the
5 limit for the speed of operation of solenoid valves in current use in an ink jet printer head is less than 1000Hz. With increasing pressure on manufacturers to increase throughput from a given production or packaging line, there is a growing demand to be able to print the
10 dots onto the substrate at rates greater than this.

In an alternative form of ink jet printer, known as an impulse jet printer, a piezoelectric crystal or other transducer is applied to or forms part of a wall of an ink
15 jet chamber having an ink inlet and having an ink outlet nozzle bore to a nozzle orifice. When a voltage is applied to the transducer, the transducer expands or flexes and causes a change in the volume of the ink jet chamber. This causes a droplet of ink to be ejected from
20 the chamber and to exit through the nozzle orifice via the nozzle bore. The transducer can be caused to flex at very high frequencies by electronic control of the frequency of the electrical pulses applied to the transducer, so that such a print head can apply dots at frequencies up to
25 15kHz or more. However, the volume of ink ejected through the nozzle orifice is dependent upon the extent of flexing of the transducer. This can be varied by varying the amplitude of the electric pulse applied to the transducer. However, each type of transducer operates consistently
30 only within a narrow percentage, typically plus or minus 10%, of the optimum operating pulse amplitude, so that

- 6 -

only a limited range of dot sizes can be achieved with a commercially available impulse jet printer. In order to increase the printed dot size it is necessary to print successive dots overlapping with one another. This limits the number of applications a given impulse jet head can be used for. Furthermore, such impulse jet heads project the droplet for only a small flight path distance, typically no more than 6 mms, since the pressure generated to expel the droplet of ink from the nozzle orifice is small. The pressure cannot be increased beyond a low threshold level, since the ink is held within the nozzle bore by the surface tension forces at the meniscus of the ink at the nozzle orifice. Also, the nozzle bore and nozzle orifice are formed in a thin wall of the chamber and the nozzle bore typically has a length to diameter ratio of less than 0.5:1. As a result the directionality of the flight path of the ejected droplets is reduced as compared to a drop on demand printer, where the nozzle bore in a jewel nozzle typically has a length to diameter ratio of 10:1 or more. Scatter of the droplets on the substrate increases if the flight path of the droplets is larger than about 2 mms for an impulse jet printer. This further limits the application of such impulse jet printers.

In a further type of ink jet printer known as a continuous ink jet printer, a charged jet of ink is ejected from a nozzle. This jet is broken up into individual charged droplets which are then steered towards the desired location on a substrate by applying varying electric voltages to deflection electrodes located adjacent the flight path of the individual charged droplets. Whilst

- 7 -

such a printer can form droplets at high frequencies and can project the individual droplets for distances of 5 to 15 cms, such printers are complex and costly to construct and operate.

5

International Patent Application No PCT/SE97/01007 describes a solenoid type valve for a drop on demand ink jet printer which is claimed to be capable of operating at frequencies of up to 3kHz. Such a valve incorporates a novel form of construction which enables the plunger to accelerate and decelerate rapidly at each extreme of its travel within the coil. To achieve this, the plunger is formed from two components, one made from an electromagnetic material so that it can be caused to move by the magnetic field generated by the coil, and a second lightweight plastic component for the distal end of the plunger. Such construction is complex and expensive. Furthermore, we have found that a drop on demand print head incorporating such a valve design does not print acceptable images. For example, at high frequencies of operation of the valve, the printed dots are uneven and there are many small satellite dots around each of the primary dots printed by the print head.

25 There thus still exists a need for a print head which is simple and yet can operate consistently at dot generation frequencies in excess of 1 kHz to generate uniformly sized droplets over a wide range of printed dot sizes using a wide range of inks or other fluids.

30

We have now devised a form of solenoid valve which can be

- 8 -

operated at speeds of up to 8kHz or more and yet print uniformly sized droplets over a wide range of dot sizes and operating frequencies. This is within the operating range of a conventional continuous jet printer. The valve
5 of the invention thus enables a drop on demand ink jet printer to print images on a fast moving substrate where the use of an impulse jet or continuous jet printer had hitherto been consider the only viable form of printing technology available, and with reduced distortion of the
10 printed image as compared to a conventional drop on demand printer. Such a valve can be made very compact, so that an array of the valves can serve one or more rows of nozzle bores in a nozzle plate to provide a compact print head with high print resolution.

15

A print head incorporating the valve of the invention can achieve the accuracy of placement of the printed dots and the long flight path of the droplets usually only achieved by slow speed drop on demand print heads. Surprisingly,
20 the valve of the invention is capable of printing accurate droplets over a wide range of sizes and frequencies without significant satellite droplet formation. The valve of the invention can be produced to a consistent performance and the movement of the plunger within the
25 coil can readily be controlled by regulating the frequency, amplitude, duration and shape of the current pulse applied to the coil using software to optimise print quality. This is to be contrasted with conventional drop on demand printers where the computer is used only to
30 regulate the open time of the valve and to relate the timing and sequence of operation of the valve to the image

which is to be produced.

Furthermore, the design of the valve of the invention readily lends itself to manufacture as an array of valves, each serving one of a plurality of nozzles in a single nozzle plate. This enables the nozzle plate and associated structure of the valve to be produced as a unitary construction with greater accuracy than where individual valves and jewel nozzles are used. A print head incorporating an array of nozzles and valves of the invention can be made to more consistent standards of performance than hitherto.

Furthermore, a print head incorporating the present invention can be made more compact than one using conventional valves. This enables small dots to be printed at closer spacing than could hitherto be achieved with a drop on demand printer.

20 SUMMARY OF THE INVENTION:

Accordingly, the present invention provides a valve mechanism for controlling the flow of fluid therethrough, which mechanism comprises a plunger member at least part of which is journaled for axial reciprocation between a rest position and an operative position within an electric coil under the influence of a magnetic field generated by that coil when an electric current passes through the coil, the distal end of the plunger extending into a valve head chamber having an outlet bore in fluid flow communication with a nozzle outlet, the reciprocation of

- 10 -

the plunger being adapted to open or close a fluid flow path from the valve head chamber through that bore, characterised in that:

- 5 a. the plunger is of a unitary construction and is made from an electromagnetically soft material having a saturation flux density greater than 1.4 Tesla, preferably greater than 1.5 Tesla, notably about 1.6 to 2.2 Tesla or more; and
 - 10 b. the plunger has a diameter of 3 mms or less, preferably less than 2.5 mms, notably less than 1 mm, and a length to diameter ratio of less than 15:1, preferably less than 10:1, notably from 3:1 to 8:1.
- 15 The term magnetically soft is used herein to denote that the material loses the magnetic field induced in it by the coil when the current in the coil ceases, in contrast to a permanent magnet which retains its magnetism. For convenience, the terms distal and proximal will be used
- 20 herein to denote that portion of a component which is located downstream and upstream respectively with respect to the flow of ink or other fluid through the valve.

The plunger of the valve of the invention is characterised

25 in that, because it is made from a specified material, it can be made smaller and lighter than plungers used in conventional solenoid valves, which are typically at least 5 mms in diameter. As a result, the plungers used hitherto have required substantial magnetic forces to move

30 them and this has required the application of high driving currents to the coils of such solenoids. In the present

- 11 -

invention, the plunger has a diameter less than 3 mms and a typical length of from 10 to 20 mms, but may be as small as 0.75 mms diameter and less than 15 mms. The optimum size of the plunger will depend upon the application to which the valve is to be put, the desired frequency of operation and the viscosity of the fluid which is to flow through the valve. In a preferred embodiment, the plunger has a diameter of less than 2.5 mms, notably 1 mm or less; a length of less than 20 mms, notably less than 15 mms; and has a length to diameter ratio of from 3:1 to 15:1, preferably from about 5:1 to 10:1.

Preferably, the material from which the plunger is made also has a coercivity of less than about 100, notably less than 50, for example about 25 amperes per metre (A/m); and a relative magnetic permeability in excess of 10,000, preferably in excess of 50,000, for example about 75,000 to 90,000.

It is preferred that the nozzle bore leading from the valve head chamber to the nozzle orifice has a length to diameter ratio of less than 8:1, preferably from 1.5:1 to 5:1, notably from 2:1 to 4:1. Preferably the nozzle orifice has the same diameter as the nozzle bore and is formed integrally with the nozzle bore in a planar member having a thickness of less than 400 micrometres.

The valve of the invention can be used wherever it is desired to eject accurately sized droplets of a fluid at frequencies in excess of 1 kHz. Thus, the valve may be used to administer accurate doses of a reagent in a

- 12 -

diagnostic test in the medical field, small amounts of a reagent in a chemical process or in analytical processes. However, the valve of the invention finds especial application in drop on demand ink jet printers where the fluid to be passed through the valve is an ink and the valve is used to print a visible or non-visible machine readable image on a substrate. For convenience, the invention will be described hereinafter in terms of this application.

10

Accordingly, the invention also provides a drop on demand ink jet printer in which droplets of ink are to be ejected from a nozzle orifice onto a substrate, characterised in that a valve of the invention is used to control the flow of ink or other fluid to that nozzle. In a preferred form of the printer of the invention, there is a plurality of nozzles orifices and the flow of fluid through each nozzle orifice is individually controlled by a valve of the invention.

20

We have found that the use of the specified materials and dimensions for the plunger overcomes many of the problems associated with the use of the conventional stainless steel plunger materials. For example, the conventional materials generate excessive heat energy when reciprocated at frequencies of 1 kHz. The use of materials having high magnetic flux saturation densities enables the plunger of the invention to respond rapidly to changes in the magnetic field generated by the coil without the generation of excessive heat. With the preferred materials, the low coercivity of the plunger material also

30

- 13 -

aids the rapid rise and fall of the induced magnetic field within the plunger under the influence of the field generated as a current is passed through the coil at low applied coil currents. This, preferably coupled with a
5 high relative magnetic permeability of the material, typically greater than 25,000, enables a high magnetic drive force to be generated rapidly between the coil and the plunger. As a result, a plunger of a given size can be accelerated rapidly by the coil by a smaller drive
10 current than a plunger made from conventional materials. This avoids the need to apply high drive currents to the coil, typically in excess of 20 amperes, as hitherto considered necessary. This again reduces the heat energy which is generated as the plunger is moved by the coil.
15 However, it may be possible to use a material of construction which has a coercivity and/or relative magnetic permeability outside the preferred ranges to achieve satisfactory results if the saturation flux density is sufficiently high.

20

The use of a material having a low coercivity also permits a reverse magnetic force to be generated rapidly by reversing the direction of the current in the coil. This reversed force can be used to slow down the movement of
25 the plunger as it reaches either or both extremes of its travel. Such magnetic braking may be used in place of or in conjunction with the bias spring conventionally used to return the plunger to its rest position. The magnetic braking can also be used to reduce the impact of the
30 plunger as it seats against the inlet to the nozzle bore. This not only increases the operating life of the plunger

- 14 -

and seal components, but also reduces satellite droplet formation as the valve closes. However, it will usually be preferred that the valve mechanism of the invention also comprises a pre-tensioned spring member as described
5 below to bias the plunger against the magnetic field generated by the coil so as to return the plunger to its rest position when an electric current is not applied to the coil.

10 These magnetic properties of the material from which the plunger is made enable high driving forces per unit mass of the plunger to be generated by the coil on the plunger. It is therefore possible to reduce the mass and hence the size of the plunger as compared to a conventional valve
15 plunger and still obtain consistent and rapid acceleration of the plunger under the influence of the coil. This enables small plungers to be used in the valves of the invention and to drive those plungers at high frequencies, typically in excess of 1kHz. Such valves can be used to
20 make compact print heads which can be operated at higher speeds than a print head using a conventional solenoid valve. Alternatively, the valve can be operated at a lower frequency but with a more viscous ink without the need to use higher operating pressures.

25 It will usually be preferred that the plunger is made from a material having as high a saturation flux density as practicable. Thus, the material may have a saturation flux density of 1.8 or higher. However, where the
30 material has a saturation flux density of 2.0 or more, for example about 2.2, we have found that such materials

- 15 -

usually contain high proportions of iron and are susceptible to corrosion by the inks normally used in an ink jet printer. Where such high iron content materials are used, it may be necessary to provide the plunger with
5 a corrosion resistant or protective surface or coating. Thus, for example, the surface of the plunger may be provided with a polymeric coating. However, it is preferred to form a metallic layer on the plunger, for example of nickel or cadmium using any appropriate
10 technique, for example electro- or vapour deposition.

Suitable materials for present use as the plunger material are available commercially and many are alloys of iron and nickel, typically containing 40 to 55% of nickel,
15 preferably an alloy containing from 45 to 50% nickel and 55 to 50% of iron. If desired, other metals, for example μ Metal, cadmium, vanadium, chromium or aluminium, may also be present in minor amounts. Preferred materials for present use are those which have a saturation flux density
20 in excess of 1.6 Tesla, for example 1.8 Tesla or more. The coercivity is preferably less than 50, notably less than about 25, amperes per metre. The relative magnetic permeability is preferably in excess of 50,000, for example 75,000 to 100,000 or more. Suitable materials for
25 present use include those ranges of alloys sold under the Trade Names Permenorm 5000 and Vacofer SI.

The plunger may be formed wholly from such materials, for example by drawing or machining a cylindrical or other
30 shaped plunger from the solid material using any appropriate technique. Alternatively, the plunger may be

- 16 -

formed from a fritted, pressed or cast polymeric or ceramic carrier having particles of a suitable ferromagnetic material or mixture of materials dispersed therein. In a further alternative, the material from
5 which the plunger is formed may be a laminate of different forms of ferromagnetic material to give a composite structure having the required overall properties. For convenience, the invention will be described hereinafter in terms of a unitary plunger formed from a solid body of
10 a single Ni/Fe alloy.

The plunger is conveniently formed by machining, rolling or extruding the desired alloy to form a length of material having the desired size and shape. During the
15 machining of the preferred materials of construction to form the plunger for the valve, the magnetic properties of the material may be affected. It may therefore be desired to subject the manufactured plunger to some form of post forming treatment so as to recover the magnetic
20 properties. Such treatments include heat treatment or mechanical impact treatments which cause a change in the crystal composition of the material. The optimum form of post forming treatment can be readily determined using simple trial and error.

25 Part of the interior of the plunger, notably where the plunger has a diameter greater than about 2.5 mms, can be removed to form an internal bore within the plunger extending from the distal end of the plunger. This
30 reduces the mass of the plunger. Surprisingly, this does not affect the magnetic properties of the plunger to a

- 17 -

significant extent and the plunger behaves magnetically as if it were a solid member. For example, an axial bore can be formed as a blind ended drilling from the distal end in a solid rod of a suitable material. Preferably, the bore
5 does not extend axially into that portion of the plunger housed within the coil when the plunger is fully retracted into the coil so that that portion of the plunger within the coil is solid. This maximises the magnetic force which acts upon the plunger during initial extension of
10 the plunger from the coil when the coil is energised. Such a method for reducing the mass of the plunger is much simpler than the complex two component structure described in PCT Application No SE97/01007.

15 Accordingly, the present invention provides a solenoid valve of the invention, characterised in that formed within the plunger and extending axially from the distal end thereof is an internal bore or cavity, whereby the mass of the plunger is reduced, said bore or cavity
20 extending axially within the plunger proximally no further than that point at which the plunger enters the bore within the coil when the plunger is fully retracted into the coil.

25 For simplicity, the invention will be described hereinafter in terms of a solid plunger.

The plunger will typically have a circular cross section and be a sliding fit within the cylindrical bore of a
30 tubular support member which extends axially within the coil, as described below, so that it can be reciprocated

- 18 -

smoothly within the coil. However, it is within the scope of the present invention for the plunger to have a polygonal or other non-circular cross section and/or for the bore in the tubular member to be non-circular, so as to provide axial fluid flow passages between the plunger and the coil. This will allow fluid to be displaced from the proximal end of the coil bore as the plunger is retracted into the coil and thus reduce fluid damping of the movement of the plunger. Alternatively, or in addition, these passages may be used to feed fluid from an inlet at the proximal end of the valve assembly to the valve head chamber at the distal end of the coil. For example, the plunger can be formed with two or more axial flats which co-operate with the walls of a cylindrical coil bore to allow fluid to flow past the plunger. Such fluid flow may also serve to cool the plunger and coil during operation of the valve.

The nozzle bore between the valve head chamber and the nozzle orifice differs from that used in either a conventional drop on demand print head or an impulse jet print head in that the length to diameter ratio of the bore is less than 8:1, typically less than 5:1, as compared to the 10:1 and greater ratio used in a conventional jewel nozzle for a drop on demand print head; and is greater than about 1.5:1 as compared to the less than 0.5:1 ratio used in an impulse jet head.

The nozzle bore diameter can be selected over a wide range. Thus, we have found that the valve of the invention can have a nozzle bore diameter of up to 400

- 19 -

micrometres where it is desired to apply a fluid having a high viscosity, for example up to 400 Cps at 25°C to coat fibres during the printing of textiles and fabrics having long fibres, typically longer than 1 mms. The valve of the invention permits the operator to select short bore lengths at large bore diameters for such high viscosity fluids without sacrificing accuracy of droplet placement. With a conventional 10:1 ratio nozzle for a drop on demand printer, the pressure required to eject such a high viscosity ink is excessive unless very large diameter bores are used. Alternatively, the bore diameter may be as small as 20 micrometres when printing high definition images using inks having a viscosity of less than 20 Cps, typically 1 to 10, notably between 2 and 5, Cps at 25°C.

The optimum combination of bore length to diameter ratio within the range 1:1 to 8:1 and bore diameters in the range 20 to 400 micrometres at a given ink pressure can readily be determined by simple trial and error tests.

We have also found that the droplet formation and droplet trajectory of a drop on demand ink jet print head using the valve mechanism of the invention are enhanced as compared to a conventional drop on demand printer. We believe that this is at least in part due to the length to diameter ratio of the nozzle bore. A jewel nozzle as used in a conventional drop on demand ink jet printer has a length to diameter ratio of at least 8:1, typically about 10:1, and such ratios have been considered necessary to achieve directionality of the flight path of droplets ejected from the nozzle orifice. However, when such a nozzle is used at droplet generation frequencies of more

- 20 -

than 1 kHz, we have found that for a given ink, printer
operating pressure and droplet flight velocity, the
printed dots may be distorted. Surprisingly, we have
found that by reducing the length to diameter ratio of the
5 nozzle bore to less than 8:1, notably less than about 5:1,
particularly to 2:1 to 4:1, these distortions can be
reduced to an acceptable level without affecting the
directionality of the flight path of the droplets ejected
from the nozzle. Furthermore, by reducing the length of
10 the nozzle bore, the pressure drop across the nozzle is
reduced, allowing a faster exit velocity to be achieved at
the nozzle orifice at a given ink pressure.
Alternatively, a more viscous ink may be ejected at a
given pressure drop across the nozzle. Surprisingly, this
15 is achieved without causing spraying of the droplets, that
is the break up of the droplet at the nozzle orifice into
a plurality of smaller droplets. This enables a higher
frequency of droplet generation to be achieved at a given
ink pressure and viscosity for a given length of flight
20 path.

However, we have also found that if the length to diameter
ratio is reduced to below about 1:1, spraying of the
droplets at the nozzle orifice begins to occur, notably
25 when the ratio is reduced to below 0.5:1, even though the
frequency of droplet formation is below than at which an
impulse jet printer having an even smaller length to
diameter ratio for the outlet nozzle operates without
causing spraying of the ejected droplets.

30

Surprisingly, we have further found that where the valve

- 21 -

of the invention is used in a drop on demand ink jet printer, problems due to drying out of the ink within the nozzle bore are reduced. In ink jet printers, drying out of the ink through loss of the solvent or carrier medium for the ink when the printer or nozzle is at rest and ink is not flowing through the nozzle bore causes the formation of solid deposits in the bore. In a conventional drop on demand or impulse jet printer, when the valve or transducer of the print head is actuated again to eject a droplet from the nozzle orifice after such a rest period, this deposit impedes the flow of ink through the nozzle bore. As a result, the initial droplets ejected from the nozzle orifice are often deformed and of uneven size. This effect is accentuated in impulse jet printers where the length of the bore is very short. Surprisingly, we have found that, despite having a lower length to diameter ratio of the nozzle bore as compared to a drop on demand printer, the valve of the invention recovers more rapidly than a conventional drop on demand ink jet printer valve after a rest period. This is effect is surprisingly enhanced when the length to diameter ratio of the nozzle bore is reduced to below 5:1, notably to from 1.5:1 to 4:1, especially from 2:1 to 3:1.

We believe that this is due at least in part to the high pressure at which ink is fed to the nozzle of a drop on demand printer which ejects the solid deposits with the initial droplets ejected through the nozzle orifice. Furthermore, the use of such elevated pressures, typically 1 to 4 bar, also projects the droplet at a greater velocity than is possible with an impulse jet print head.

- 22 -

The projection distances which can be achieved with the valve of the invention are comparable to those which can be achieved with a conventional continuous jet ink jet printer. However, the construction and operation of a drop on demand ink jet print head using the valve of the invention are simpler than for a continuous jet print head.

We have found that the amount of fluid remaining in the bore to the nozzle orifice of the valve of the invention after the ejection of a droplet from the nozzle orifice is usually smaller than can be achieved with a conventional drop on demand print head. This is particularly the case where the length to diameter ratio of the nozzle bore has the effect of achieving a nozzle bore volume which is approximately equivalent to the volume of ink which is to be ejected at each actuation of the valve, notably where the length to diameter ratio is about 2:1. As a result, the damping effect of the inertia of this fluid on the movement of the plunger of the valve of the invention is reduced, further assisting rapid movement of the plunger under the influence of the coil thus assisting high frequency operation of the valve.

The nozzle bore diameter can be selected over a wide range. Thus, the nozzle bore diameter may be up to 400 micrometres where it is desired to apply a fluid having a high viscosity, for example up to 400 Cps at 25°C to coat fibres during the printing of textiles and fabrics having long fibres. The valve of the invention permits the operator to select short bore lengths at large bore

- 23 -

diameters for such high viscosity fluids without sacrificing accuracy of droplet placement. With a conventional 10:1 ratio nozzle for a drop on demand printer, the pressure required to eject such a high viscosity ink is excessive, unless very large diameter bores are used, which reduces the definition of the image which is printed. Alternatively, the bore diameter may be as small as 20 micrometres when printing high definition images using inks having a viscosity of less than 20, typically 1 to 10, notably between 2 and 5, Cps at 25°C. The optimum combination of bore length to diameter ratio within the range 1:1 to 8:1 and bore diameters in the range 20 to 400 micrometres at a given ink composition and pressure can readily be determined by simple trial and error tests.

We believe that the enhanced directionality of the flight path of droplets ejected from the nozzle orifice of the valve of the invention may also be due at least in part to achieving a smooth internal surface of the nozzle bore. This reduces boundary friction and eddies within the fluid flowing through the bore. We also believe that the use of a nozzle orifice which is of substantially the same diameter as the nozzle bore upstream of the nozzle orifice is a major factor in reducing loss of directionality in the reduced length to diameter ratio bores in the valve of the invention. We believe that a further factor in improving the directionality of the droplet trajectory is achieved by a preferred form of construction of the nozzle.

- 24 -

In a conventional drop on demand print head, the nozzle orifice is provided by a jewel nozzle which is set into the distal end of a bore in the nozzle plate. We have found that there are minor errors in aligning the nozzle accurately within its seat. As a result, the flight path of the droplets ejected from such a nozzle may be inaccurately directed. Whilst this effect can be compensated for with a single nozzle print head, this is more complex and difficult with a multi-nozzle print head.

With a conventional 10:1 length to diameter bore, the collimating effect of the bore largely ensures that a given nozzle will perform with consistent flight path directionality, so that compensating for any inaccuracy in alignment of the nozzle can be achieved. However, where the length to diameter ratio of the nozzle bore is reduced, it would be expected that this would reduce the collimating effect and thus the consistency of the directionality of the droplet flight path from such a nozzle.

We therefore prefer to form the nozzle orifice as the distal outlet of the nozzle bore and to dispense with the use of a separate jewel or other nozzle member. In a preferred embodiment of the invention, the valve of the invention is used with a nozzle plate having a plurality of nozzle bores therethrough which are preferably formed substantially simultaneously in a single operation so that the nozzle plate has a unitary construction without the use of jewel nozzles. Such a simple unitary nozzle structure can readily be made using a wide range of techniques and overcomes the problems associated with

- 25 -

misalignment of jewel nozzles in a conventional multi-nozzle print head.

The nozzle orifice and bore are formed as a unitary
5 structure, for example concurrently as a bore is cut or otherwise formed in a plate upon which the valve mechanism is to be mounted. For example, the bore/nozzle orifice is formed in a nozzle plate by a laser, microelectro-machining or etching, needle punching or other techniques.
10 The nozzle plate can be from 50 to 400 micrometres thick so as to achieve the desired length to the bore. At such thickness, the nozzle plate takes the form of a metal or other foil which is mounted in a suitable support member to provide a rigid and mechanically strong nozzle plate
15 assembly. We have found that by forming the nozzle bores simultaneously in a multi-nozzle nozzle plate, problems due to misalignment of the bores with one another are minimised.

20 We have also found that by selection of the bore forming technique, the walls of the bore are sufficiently smooth to reduce flow separation and the formation of eddies at the interface between the bore walls and the fluid flowing through the bore. Furthermore, such techniques may also
25 be used to form other features on the nozzle plate which enhance the operation of the valve. For example, electro-machining or etching of a metal foil can be used to form the bores/nozzle orifices in the plate and also to form a raised lip or ridge around the inlet to the bore leading
30 to the nozzle orifice. This provides a localised pressure point between the distal end face of the plunger and the

- 26 -

nozzle plate to assist the formation of a fluid tight seal when the plunger is in the valve closed position. Alternatively, where a needle is used to form the bore in a metal foil, this will cause the foil to deform and form
5 a slightly larger diameter belled entry to the bore which will assist smooth flow of fluid into the bore from the valve head chamber. The penetration of the needle through the foil may also polish the surface of the foil, and hence the internal wall of the bore which is formed, as
10 the surface of the needle slides over the material of the foil. Similarly, the use of a laser to form the bore in a metal, ceramic or plastic foil may also form a polished surface to the walls of the bore, notably where the laser beam is pulsed for very short periods, typically less than
15 1 nanosecond, to reduce the formation of deposits of material which has been ablated from the plate in forming the nozzle bore around the lip of the bore.

Accordingly, from another aspect the present invention
20 provides a solenoid valve of the invention, characterised in that the nozzle orifice and the bore from the valve head chamber to the nozzle orifice are formed as a unitary construction. Preferably, the outlet nozzle and the bore are formed as a bore within a foil nozzle plate having a
25 thickness of up to 400 micrometres, the bore having a length to diameter ratio of less than 8:1, preferably 1:1 to 5:1. Preferably, the bore has a polished internal surface so as to reduce flow separation or eddies in fluid as it flows through the bore. Preferably, the bores in
30 the nozzle plate are formed substantially simultaneously.

- 27 -

As stated above, the valve mechanism preferably also comprises a spring member to provide the bias to return the plunger to its rest position when a current is not applied to the coil. Typically, the spring is a
5 compression spring and acts to bias the plunger against the inlet at the proximal end of the bore to the nozzle orifice, so that the rest position of the plunger is in the valve closed position. When a current is applied to the coil, this opposes the bias of the spring and moves
10 the distal end of the plunger away from the bore inlet to open a flow path from the valve head chamber to the nozzle orifice. However, it will be appreciated that the rest position may be the valve open position and the operative position is the valve closed position. For convenience,
15 the invention will be described hereinafter in terms of the rest position being the valve closed position.

The spring member is pre-tensioned, for example from 50 to 80% of the travel of the compression of the spring is
20 taken up by the pre-tensioning, since we have found that such pre-tensioning enables the spring to apply a consistent bias force against the movement of the plunger over the remainder of the compression of the spring during movement of the plunger. We have found that the use of a
25 conical spring is of especial benefit since such springs can readily be fitted within the dimensions of the valve head chamber and will tend to be self centring during the assembly of the valve mechanism, whereas conventional cylindrical coil springs do not. Furthermore, the use of
30 a conical spring reduces the mass and hence inertia of the spring, further aiding rapid response of the spring to

- 28 -

- movement of the plunger. It is particularly preferred to use a conical coil spring which is pre-tensioned to the last two turns of the spring, since we have found that such a spring responds rapidly to the movement of the plunger and the pre-tensioning enables the spring to exert a significant bias force over a small additional compression of the spring. This aids the compact size of the valve of the invention.
- 10 However, it will be appreciated that the bias effect could be applied alternatively or in addition to that applied by the spring by applying a current to the coil which opposes the movement of the plunger. Such opposing current can be applied under the control of electronic switching using conventional techniques and software, for example as described below.

- Fluid can be fed to the valve head chamber by any suitable means, for example by one or more radial inlet ports in the side wall of the chamber. Alternatively, as described above, the plunger and/or the internal wall of the tubular support for the coil can be formed with axial flats or passages so that fluid flows axially past part or all of the plunger within the coil. The fluid lubricates the movement of the plunger within the coil and can also act to cool the coil at high current loadings and/or high frequencies of operation of the valve. Where the valve mechanism is used as part of an array print head having a plurality of nozzles, it will usually be preferred to feed at least part of the ink or other fluid by means of a manifold plate in which inter-connecting valve head

- 29 -

chambers are formed so that ink may flow freely along an elongated chamber or gallery. This aids uniform flow to each nozzle bore in the associated nozzle plate as described above.

5

As indicated above, the solenoid valve also comprises a valve head chamber which houses the distal end of the plunger and is provided with the outlet nozzle bore to the nozzle orifice. Such a chamber typically is of generally
10 circular cross section and has a transverse end closure wall having the outlet and the nozzle bore to the nozzle orifice formed therein. If desired, the tubular support member for the coil can be longitudinally extended to provide the radial walls of the valve head chamber. In
15 one embodiment of such a construction, the tubular member is formed as a cylindrical tube having one end closed to form the transverse terminal wall of the valve head chamber, the wall being pierced by a bore whose free end provides the nozzle orifice. Such an assembly can readily
20 be formed by electroforming or laser etching of a silicon or ceramic member to high accuracy using automated techniques.

The valve mechanism is preferably used in co-operation
25 with a plurality of closely adjacent valve mechanisms, each serving one or more discrete nozzle orifices to form an array type print head capable of applying a plurality of dots of fluid to a substrate to create a two dimensional image on a substrate. Such an array can be
30 formed by mounting the outlet end of the valves upon a nozzle plate with a bore through the plate providing the

- 30 -

nozzle bore from the valve head chamber of the valve to the nozzle orifice. Preferably, the valves are located in staggered rows to achieve as close a spacing for the nozzle orifices in the nozzle plate. If desired, the

5 nozzle bores from each valve head chamber can be at an angle to permit the valve bodies to be offset from the centre line of the nozzle plate to enable the nozzle orifices to be more closely spaced. In a particularly preferred embodiment, the nozzle plate is provided with a

10 series of upstanding tubes, each in register with one of the bores through the plate. The tubes serve as the support for the coil of the valve and the plunger reciprocates within that tube. The distal end portions of the tubes adjacent the nozzle plate, or the proximal

15 portion of the bore in the nozzle plate, serves as the valve head chamber of the valve mechanism. Such arrays can be formed from ceramic or silicon materials using automated techniques and the nozzle orifice can be provided either by a jewel nozzle set into the distal end

20 of the bore through the nozzle plate or by forming a suitable nozzle orifice in the end of a blind end bore in the nozzle plate as described above. Such assemblies can be formed on a very small scale enabling miniaturisation of the valve structure to be achieved. It is preferred to

25 provide the nozzle plate as a metal, ceramic or other foil having the bores formed therethrough as described above and to mount that plate so that the bores therein are in register with the distal ends of the plungers of the valves. In this case, the valve head chambers can be

30 individually formed in the surface of the foil or in an intermediate plate located between the valve coil support

- 31 -

members and the nozzle plate.

However, we have found that the flow of ink or other fluid to the individual bores and nozzle orifices is enhanced if
5 the intermediate plate is formed with a continuous chamber which provides a combined valve head chamber for all the valves in the print head assembly. In such a construction, the seal between the distal end face of each plunger and the registering bore in the nozzle plate
10 provides adequate isolation of flow through each of the nozzle bores and orifices. The opposing faces of the nozzle plate and the distal end of the plungers are preferably provided with sealing means to assist the formation of a fluid tight seal when each plunger is in
15 the closed position. For example, the end face of the plunger can be provided with a natural or synthetic rubber or polymer face which deforms to provide a seal against the opposed face of the nozzle plate. The face of the nozzle plate can be provided with one or more annular
20 raised ribs or the like which provide localised raised pressure areas to assist formation of the fluid tight seal. Such raised areas can readily be formed on the face of the nozzle plate during the electro-forming or etching of the nozzle plate.

25
If desired the raised areas on the nozzle plate can be formed from a flexible material to cushion the impact of the end face of the plunger against the nozzle plate. Such deformation may also assist formation of the fluid
30 tight seal where the end face of the plunger does not carry a rubber or similar pad. If desired, the pad

- 32 -

carried by the end face of the plunger can be formed from a material which undergoes cold creep or deformation under the load of the bias spring urging the plunger into the valve closed position. Such creep may form a nipple or
5 other projection which extends into the proximal portion of the nozzle bore in the nozzle plate. Upon reciprocation of the plunger, this projection repeatedly wipes at least the initial part of the proximal portion of the nozzle bore and displaces solid deposits which may
10 have deposited upon the wall of the bore. This may assist in reducing initial drop deformation after rest periods of the valve. To assist the operation of this projection, the mouth to the inlet to the bore through the nozzle plate may be belled, as may occur when a needle is used to
15 form the bore in the nozzle plate.

The invention also provides a print head for use in a drop on demand print head in which a plurality of solenoid valve mechanisms of the invention are each mounted in
20 register with one of a plurality of bores through a nozzle plate, characterised in that the nozzle plate is a foil member having the bores therethrough and each bore is provided with a valve head chamber adapted to receive the distal end of the plunger of the valve mechanism
25 associated therewith. Preferably, the valve head chambers are provided by a single chamber extending over a plurality of the bores in the nozzle plate to provide a common flow path to the bores and their associated plungers. Preferably, the nozzle plate is provided with
30 two or more rows of nozzle bores, which may be staggered to assist close packing of the valve mechanisms associated

- 33 -

with each nozzle bore.

Where the valves of the invention are mounted in close proximity with one another to form a print head containing
5 a plurality of nozzle orifices, it is preferred to provide each valve mechanism with a metal housing to the coil thereof which acts not only as a return path for the magnetic field generated by the coil within it, but also acts as a magnetic screen so as to reduce cross talk
10 between the magnetic fields generated by one coil and the coil of an adjacent valve mechanism. Typically, such a metal housing is made from μ -metal, aluminium or stainless steel and also acts as a rigid housing for the components of the valve mechanism. Thus, the housing can be of a
15 generally cylindrical form and can be crimped radially inwardly at each end thereof to retain the coil assembly. The distal end of the metal housing can be crimped or otherwise secured to the nozzle plate where the nozzle plate carries upstanding tubular members as described
20 above.

Fluid can be fed to the valve head chamber by any suitable means, for example by one or more radial inlet ports in the side wall of the chamber. Alternatively, the plunger
25 and/or the internal wall of the tubular support member for the coil can be formed with axial flats or passages so that fluid flows axially past part or all of the plunger within the coil so that the fluid lubricates the movement of the plunger within the coil. The flow of fluid past
30 the plunger can also act to cool the coil at high current loadings and/or high frequencies of operation of the

- 34 -

- valve. Where the valve mechanism is used as part of an array print head having a plurality of nozzles, it will usually be preferred to feed at least part of the ink or other fluid by means of a manifold plate in which inter-
5 connecting valve head chambers are formed so that ink may flow freely along an elongated chamber to aid uniform flow to each nozzle bore in the associated nozzle plate as described above.
- 10 The valve of the invention is capable of being operated at high frequencies, typically in excess of 1.5 kHz, for example at from 2 to 5 kHz, and as described above finds especial application as the solenoid valve in a drop on demand ink jet printer head. In such an application, the
15 ability to form the valve as a compact item reduces the overall size of the print head. The low inertia of the plunger enables high droplet generation frequencies to be achieved at low levels of current applied to the coils of the valve, reducing the power consumption of the valve or
20 to enable high drive forces to be generated between the plunger and the coil for the application of viscous inks, for example in the application of inks or dyes to long pile fabrics or textiles as described above. However, it will be appreciated that, as stated above, the valve
25 mechanism of the invention may be used wherever a small, high speed valve is required.

In a conventional drop on demand printer, the operation of each solenoid valve is triggered in response to a signal
30 from a computer or microprocessor, which determines which valve is opened and when so as to print the desired image.

- 35 -

We have found that the control the operation of the valve using software has a number of other significant benefits which enable the valve of the invention to deliver high quality printed images at much higher frequencies that has
5 hitherto been considered possible for a drop on demand print head.

Thus, it is particularly preferred to use software to calibrate the valve so that under specific conditions it
10 delivers a consistent droplet of ink through the nozzle orifice. With conventional designs of solenoid valve, it is necessary to compensate for minor variations in dimensions and materials of the manufactured valve by physically adjusting the axial travel of the plunger so as
15 to vary the size of the flow path created when the plunger is withdrawn from sealing engagement with the transverse end wall of the valve head chamber or the tube leading to the nozzle orifice. This will affect the size of the dot ejected from the nozzle orifice and the objective of the
20 calibration process is to achieve a uniform droplet size from all the nozzle orifices in a print head under the same printing conditions. The conventional design of solenoid valve incorporates a stop within the bore of the tubular support for the coil, which stop provides a
25 physical limit to the axial movement during retraction of the plunger. In such a conventional valve design, the air gap between the proximal end of the plunger and the distal face of the stop is adjusted, for example by making the stop a stiff push fit or a screw fit within the tubular
30 support, so that it can be moved axially within the bore of the tubular member to achieve the desired air gap.

- 36 -

Such adjustment of the air gap is tedious and time consuming and is prone to operator error.

We have found that software can be used to set a specific point in the retraction of the plunger at which the plunger movement halts. This point can readily be adjusted by simple modification of a parameter of the software, for example by keyboard input of a new value for that parameter. Such adjustment can be achieved very accurately and the calibration carried out for a number of sets of printing conditions so that the current pulse size and duration required to achieve given droplet sizes can be determined and stored, for example in as a machine readable code on a magnetic disc, look up table in a memory chip or other storage medium, for future use with that valve. The calibration can be achieved simply and at smaller increments of droplet size than is possible with screw adjustment of the stop in conventional design of solenoid valve.

In carrying out the calibration, droplets are printed onto a substrate whilst operating the valve under standard conditions and at a given electric current pulse amplitude and duration applied to the coil. The printed dot is examined by any suitable means and the amplitude and/or duration of the electric pulse raised or lowered to achieve the desired dot size. Such a process can be carried out manually. However, it is preferred to carry out this process automatically by inspecting the printed dot using a CCD camera or other inspection means and comparing the form of the printed dot with parameters for

- 37 -

the required dot. Such comparison and subsequent adjustment of the current pulse can be carried out using a suitably programmed computer. It is especially preferred to monitor the diameter and circularity of the printed dot and the presence of satellite small dots adjacent the desired dot using a CCD array or camera and comparing the dot characteristics with those held in a look up table which identifies the correction which needs to be applied to the current pulse applied to the coil to achieve the desired printed dot characteristics. The optimum variation in the operation of the valve mechanism, for example to increase or reduce the open time of the valve, can be determined by trial and error tests. These optimum values of the variation then stored in a look up table or other storage medium to provide one of the parameters against which the printed dot and the operation of the print head is assessed.

The use of a CCD camera or array and computer to inspect the droplet of ink as it is ejected and/or the printed dot and to modify the current applied to the coil of the valve also has applications during the operation of the valve on-line during printing of images. Thus, the computer can be programmed to decelerate the movement of the plunger at each end of its travel. We have found that this reduces splatter of the ink from the nozzle orifice due to sharp impact of the plunger against the seal members at the entry of the bore between the valve head chamber to the nozzle orifice. The use of software can also be used to compensate for fluctuations in the viscosity of the ink due to temperature variations or other reasons; variations

- 38 -

in voltage applied to the different coils in an array of print heads which are operated simultaneously; and to compensate for other changes in operating conditions, for example the use of a different ink, which require changes in the form and size of the electrical pulse applied to the coil of the valve. The use of software can also be used to hold a valve in the open position to print a continuous line of ink in place of the series of overlapping dots achieved with present print head operating techniques; and to vary the open time of the valve for the initial droplets ejected from the nozzle orifice following a rest period of the valve.

In all the above cases the operation of the valve is modified by the computer in response to a signal from the CCD camera or other mechanism used to inspect and monitor the droplet of ink as it is ejected and/or the printed dot and to compare the observed droplet or dot to parameters held in a memory of the computer or another storage medium so as to determine what modification, if any, is required to the current applied to the coil so as to achieve the desired dot.

The invention thus provides a print head of the invention operated under the control of a computer in combination with a mechanism for observing the printed dot of ink or other fluid applied to the substrate, the computer being programmed to detect differences between the observed dot and the desired dot and to apply a correction to the current applied to the coil so as to maintain the desired observed dot parameters.

- 39 -

Such a combination enables the printed dot quality to be monitored and corrected on-line during operation of the printer. Hitherto, the print quality was observed
5 subjectively by the operator of the printer and a correction to the operation of the printer applied manually. The ability to use the software on-line to achieve monitoring and correction of print quality is a major benefit to the operator and can achieve virtually
10 instantaneous correction of fluctuations in print quality.

The monitoring and correction may be achieved using conventional software and hardware techniques and designs. The dot quality can be monitored continuously and a
15 correction applied in response to the average of three or more successive dots. Alternatively, the printed dot quality can be monitored at intervals, for example every second or at intervals of every twenty operations of the valve, and any correction applied once the printed dot
20 deviates by more than say 5% for any one or more of the parameters used to assess the quality of the printed dot.

Typically, the monitoring of the printed dot quality will be used to apply a signal to vary the open time of the
25 valve.

It will be appreciated that the signal indicating that some variation of the operation of the valve is required may be provided from an external source rather than from
30 the on-line scanning of the printed dot. Thus, a sensor may monitor the operating temperature of the printer

- 40 -

and/or of the ink fed to the valve, since this will affect the viscosity and hence the jet-ability of the ink. Alternatively, such sensors may monitor: the voltage applied to the valve mechanism, for example the voltage drop which occurs when a plurality of valves are operated simultaneously from a single power source; the time for which a specific valve has rested between printing operations, the frequency of operation of a valve and so on. These sensors may then address a series of look up tables which then set the variation of the open time required to reduce defects in quality of the printed dot if that parameter being monitored varies from a predetermined optimum value.

15 It is preferred that the quality of the printed dot from each nozzle be monitored individually. However, if desired the printed dot quality from groups of nozzles may be monitored collectively.

20 In the conventional computed control of the operation of a valve in a drop on demand printer, simple single bit signals are used to open and shut the valve since all that has been required hitherto is that the computer instruct the valve when to open and shut the valve so as to print a dot of the required size. However, the ability to vary the operation of each valve individually during the operation of the printer in response to many inter-related factors requires the transmission of more complex signals than simple open and shut instructions. We have found

25 that it is desirable to transmit signals in byte format so that the amount of information transmitted can accommodate

30

- 41 -

the permutations of operating parameters desired. Thus, for example, the use of byte form signal transmission offers 256 possible graduations of open time of the valve. This enables the amount of ink deposited in each printed
5 dot to be varied over a finely graduated range by providing a look up table with 256 individual addresses therein from which the computer controlling the operation of the printer can instruct the open time of the valve to be selected. This enables a true grey scale image to be
10 printed using a drop on demand print head, which has not hitherto been considered practical. The use of byte signal transmission enables a wide selection of values for variation of a given operating parameter to be transmitted and responded to rapidly and accurately, further enhancing
15 the speed and accuracy of operation of the print head.

The drop on demand printer of the invention may be used to apply a wide range of visible or non-visible ink compositions to a wide range of substrates for a wide
20 range of applications. Such ink compositions can be of any suitable composition and viscosity. However, we have found that the print head of the invention can be used successfully to apply inks to long pile fibres in fabrics or textiles without the need to use very high viscosity
25 inks as has hitherto been considered necessary to ensure even coating of the fibres with the dye of the ink. Thus, in place of inks having viscosities in excess of 250 Cps at 25°C, we have found that good results can be achieved using inks of from 60 to 120 Cps applied at frequencies of
30 about 2 kHz. The ability to use low viscosity inks enables the printing to be achieved using smaller nozzle

- 42 -

orifices, which increases the definition of the pattern printed on the fabric. It also enables the operator to select inks from a wider range than hitherto and to operate the printer at lower ink pressures, which reduces
5 the need for special modification of the printer and the risk of failure of components.

Many fabrics, both woven and non-woven, have a surface which presents free ends of fibres generally normal to the
10 plane of the fabric. Such fabrics include felted materials where fibres in a randomly orientated mass are compressed, optionally in the presence of a bonding agent such as an adhesive; materials woven from strands made up
15 from a plurality of individual fibres where the surface of the fabric has been, brushed, teased, abraded or otherwise treated to separate some of the fibres from within the strands to form a fluffy surface to the material, for
20 example a brushed nylon; woven materials made from materials which are inherently fluffy, such as knitted or woven angora, merino or cashmere wools or cotton terry towelling; and carpet type materials such as velvets, velours and tufted carpets where individual lengths of strands or fibres are knotted, sewn, glued or otherwise
25 secured to a sheet member, typically a reticulate backing sheet, whereby the free ends of the strands or fibres form a pile which extends generally normal to the plane of the backing or where loops of the strands or fibres are formed extending generally normal to the plane of the backing and the free ends of the loops severed to form the pile. For
30 convenience the term pile fabric will be used herein to denote all such types of material where individual fibres

- 43 -

or strands comprising groups of fibres extend generally normal to the plane of the material to provide a pile effect surface to the material.

5 It is often desired to form patterns or images upon the surfaces of pile fabrics, for example a coloured pattern. This can be achieved by interweaving different coloured, textured or other material strands of wool or other material into the fabric as it is being made. However,
10 this is difficult and time consuming, especially where the pattern is complex and/or a plurality of colours or textures are desired. Such use of a plurality of different strands is becoming progressively uneconomic in the large scale manufacture of commodity materials, such
15 as patterned carpets.

It has therefore been proposed to manufacture the pile fabric from neutral or uniformly coloured fibres or strands and to apply a colour to the pile fibres after the
20 fabric has been woven or otherwise manufactured. The colour is typically an ink applied by any suitable printing technique. A printing technique which is used is an ink jet printing technique using a drop on demand type of printer. The ink is desirably applied at the rate of
25 about 300 to 400% by weight of the fibre to be coloured and needs to penetrate substantially uniformly throughout the strands formed from the individual fibres and yet not load the support material of the fabric with excessive amounts of ink or dye. If a very mobile ink having a
30 viscosity of about 10 cPs at 25°C (as is commonly used in an ink jet printer) is used, it will run down the length

- 44 -

of the strands and form an intense coloration at the base of the pile, leaving the top portion of the pile inadequately dyed, and little penetration of the colour into the strands will take place. It is therefore
5 necessary to increase the viscosity of the ink in order to ensure that it runs down the fibre at a sufficiently slow rate for uniform penetration of the ink into the strands and coverage of the surface of the individual fibres takes place. The longer the pile, the greater this problem
10 becomes. With long pile fabrics, that is those with a pile length of about 2 mms or more, it is necessary to use inks having a viscosity of from 250 to 500 cPs at 25°C.

Such viscous inks are difficult to jet through the very
15 fine orifice nozzles of a conventional ink jet printer and pressures far in excess of those for which the printer is designed would be required. Furthermore, if a low viscosity ink were applied at such high pressures, it would issue from the nozzles as high powered jets and
20 cause the individual strands to bend over and thus prevent the ink from contacting other strands in the pile. It is therefore customary to use nozzles having orifices which are progressively greater as the length and closeness of the pile increases. Thus, for a carpet having a pile
25 length of 3 mms or more it is necessary to use an ink having a viscosity of about 300 cPs, a pressure of about 2 bar and nozzle diameters of typically 500 micrometres in diameter so that the viscous ink can be ejected in sufficient amounts to attain the desired loading of ink on
30 the individual strands.

- 45 -

Whilst the use of large diameter nozzles for high viscosity inks enables the ink to be deposited on the strands of the pile to achieve substantially uniform coloration of the individual strands and fibres, the size of the droplets issuing from the nozzle are sufficiently large to cause perceptible loss of definition in the printed pattern. Furthermore, the size of the droplets also results in adjacent droplets applied to the pile contacting one another, which results in colour bleeding where the droplets are of different colours.

Surprisingly we have found that the use of a drop on demand print head of the invention which operates at frequencies greater than 1 kHz, enables the size of the droplets being printed and hence the pressure required to eject them through comparatively small nozzle orifices to be reduced. This reduces the problems of colour bleed and enhances the definition of the printed image or pattern. Furthermore, we have found that it becomes possible to omit individual printed droplets from the printed pattern and thus print a blank area within the image which is not visually perceptible but which acts to provide a gap within the printed strands to act as a barrier to colour bleeding. Such a gap may also be printed as a black line defining the edges of areas printed with different colours, which enhances the perceived definition of the printed image or pattern.

Accordingly, from another aspect, the present invention provides a method for applying an image forming composition to a pile fabric using a drop on demand ink

- 46 -

printer of the invention, characterised in that the printer is operated at a drop generation frequency of at least 1 kHz. Preferably, the pile fabric has a pile length of at least 2 mm and the printer is operated at a pressure of less than 3 Bar, notably at from 1.5 to 2.5 Bar. Preferably, the nozzle orifices have a diameter of from 250 to 600 micrometres, notably about 500 micrometres.

- 10 We have also found that the use of such a printer of the invention enables individual control of the printing of the dots of the image so that accurate over-printing of dots can be achieved. It is thus possible to enhance the colour range and colour intensity which can be achieved.
- 15 Such a printer thus enables an infinite scaling of the colour hues which can be achieved.

The invention can be applied to the application of any form of image to any pile fabric. However, the invention is of especial application in the application of a water and/or solvent based ink composition to form a patterned image on a long pile fabric having a pile length of about 2 to 5 mm as measured from the top surface of the sheet member to which the strands or fibres forming the pile surface of the fabric are secured. Such pile fabrics can be velvets or twist pile carpets, but for convenience the this aspect of the invention will be described in terms of printing a multi-colour pattern on a tufted pile carpet in which the strands containing a plurality of individual fibres are secured to a reticulate backing sheet by adhesive. Such carpets can be made by any suitable

- 47 -

technique and the invention can be applied during the fabrication of the carpet. after the strands have been secured to the backing sheet or can be applied after the carpet has been manufactured in a separate colour printing operation. As indicated above, the strands are made from a neutral tint fibre, for example from a natural washed wool fibre, optionally in admixture with one or more natural coloured polymer fibres, for example polyester or polyamide fibres. If desired, the fibres or the strands formed from the fibres may be given one or more treatments to render the fibres receptive to the ink composition to be applied to them. The fibres, their formation into strands, the treatment of the fibres or strands and the formation of the carpet can all be those conventionally used in the manufacture of a tufted carpet.

For convenience, this aspect of the invention will be described hereinafter in terms of the application of ink to a neutral washed wool fibre tufted carpet shortly after the pile has been formed on a reticulate woven polypropylene backing sheet.

In a preferred embodiment of this aspect of the invention, the printer is one in which the solenoid valve mechanism for controlling the flow of fluid to the nozzle orifice comprises a plunger member journaled for axial reciprocation between a rest position and an operative position within an electric coil under the influence of a magnetic field generated by that coil when an electric current passes through the coil, the distal end of the plunger extending into a valve head chamber having an

- 48 -

outlet nozzle bore, the reciprocation of the plunger being adapted to open or close a fluid flow path from the valve head chamber through that bore, characterised in that:

- 5 a. the plunger is of a unitary construction and is made from an electromagnetically soft material having a saturation flux density greater than 1.4 Teslar, preferably about 1.6 to 1.8 Teslar, and preferably also a coercivity of less than 25 ampere per metre and a relative magnetic permeability in
10 excess of 10,000; and
- b. the plunger has a diameter of less than 3mm and a length to diameter ratio of from 3:1 to 20:1; and
- c. the nozzle bore leading from the valve head chamber to the nozzle orifice has a length to diameter
15 ratio of less than 8:1, preferably from 1.5:1 to 5:1, notably from 2:1 to 4:1.

In printing onto fabrics, it is often necessary to print lines of ink. We have found that the valve of the
20 invention can be held in the open position for prolonged periods to print continuous lines on the substrate which have a length equivalent to at least three individual printed dots. With conventional solenoid valves, it has been considered necessary to pulse the current to the coil
25 so as to form overlapping dots of ink on the substrate. In practice this often leads to the valves burning out due to the high currents applied to the coil to move the plunger from its initial rest position into the valve fully open position. We have found that the amplitude of
30 the current flowing through the coil required to hold the plunger of a valve of the invention in the valve open

- 49 -

position is surprisingly much less, typically 80 to 50% less, than the current required to move the plunger initially away from its rest position. By applying a current pulse which has an initial amplitude sufficient to
5 move the plunger from its rest position to the valve open position and then reducing this amplitude to a lower value for the remainder of the pulse, it is possible to hold the valve open for prolonged periods so as to print lines of ink on the substrate.

10

Accordingly, the present invention also provides a method for operating a drop on demand ink jet printer incorporating a valve of the invention to print a line of ink upon a substrate, which line has a length equivalent
15 to at least three individual printed dots, characterised in that the plunger of the solenoid valve is held in the valve open position by applying a current to the coil of the valve which current has an amplitude of less than 50% of that required to move the plunger initially from its
20 rest position.

The ability to hold the valve of the invention in the open position for long periods as described above is of particular advantage in the printing of long pile fabrics
25 where solid blocks of colour are often required. Printing using individual droplets of ink or dye results in an image in which the intensity of the printed image is weaker at the junction of adjacent dots. By holding the valve in the open position, the image is printed as a
30 continuous line of substantially uniform intensity.

- 50 -

We have found that the valve of the invention can be operated with inks having viscosities of from 50 to 150 Cps at 25°C and with nozzle orifices of from 80 to 250 micrometres in applying ink to such long pile fabrics.

5

Accordingly, the present invention provides a process for applying an ink or dyestuff having a viscosity of from 50 to 150 Cps at 25°C to a fabric or textile having a pile length of 1 mms or more using a drop on demand print head
10 incorporating a valve of the invention having a nozzle orifice of from 80 to 250 micrometres and operated at a frequency of 1 kHz or more.

DESCRIPTION OF THE DRAWINGS:

15

A preferred embodiment of the invention and its operation under on-line software control will now be described by way of illustration only and with respect to the accompanying drawings, in which Figure 1 is a diagrammatic
20 axial cross section through a valve of the invention; Figure 2 is an axial cross section through a drop on demand ink jet print head incorporating an array of the valves of Figure 1; Figure 3 is plan view of the nozzle plate of the print head of Figure 2; Figure 4 is a
25 diagrammatic block diagram of an array of Figure 2 in combination with a CCD camera for monitoring the quality of the printed dots and a computer for establishing what variation to the frequency, form, shape and amplitude of the electrical pulse applied to the coil of the valve of
30 Figure 1 is required to compensate for any deviation in the quality of the observed printed dot; Figures 5 to 7

- 51 -

illustrate variations in the construction of the valve of Figure 1; Figure 8 illustrates an alternative form of the print head of Figure 2; Figure 9 shows a schematic depiction of a solenoid valve which is suitable for use with the calibration of the valve using software according to that aspect of the present invention; Figure 10 shows in diagrammatic form an apparatus for use in this aspect of the invention; Figures 11 to 13 illustrate alternative forms of the apparatus of Figure 10; Figures 14 and 15 show diagrammatically a valve and printer in which the current applied to the coil is modified to decelerate the plunger at either extreme of its travel; and Figure 16 illustrates the form of current pulse applied.

15 DESCRIPTION OF THE PREFERRED EMBODIMENT:

The valve of Figure 1 comprises a plunger 1 which is journaled as a close, free sliding fit for axial reciprocation in a stainless steel tube 2. Tube 2 has a thin insulating coating or sleeve (not shown) formed upon its outer face and supports a coil 3 wound upon it. Coil 3 is supplied with an electric current from a source (not shown) under the control of a computer 20, shown in Figure 4. A stop 4 is mounted at the proximal end of tube 2 to limit the axial retraction of plunger 1 within tube 2. The coil 3 is encased in a metal cylindrical housing 5.

The above assembly is mounted in a support housing 10 which extends axially beyond the distal end of the coil and has a transverse end wall 11 which carries a jewel nozzle 12. In the embodiment shown in Figure 1, housing

- 52 -

10 has an axially extending internal annular wall 13 which forms the radial wall of the valve head chamber 14 into which the distal end of the plunger extends. The distal end of the plunger 1 carries a terminal rubber or other
5 sealing pad 15 which seats against the proximal end face of jewel 12 in sealing engagement. A pre-tensioned conical spring 16 biases plunger 1 into sealing engagement with the face of the jewel as shown in Figure 1, the rest or valve closed position.

10 Plunger 1 is made from a ferromagnetic alloy having a saturation flux density of 1.6 Teslar, a coercivity of 0.2 a/cm and a relative magnetic permeability of 100,000. In order to reduce the mass of the plunger 1, it may have a
15 blind internal bore extending from the distal end thereof. However, this bore should not extend beyond line A-A shown in Figure 1 when the plunger is in its rest position. The plunger has a diameter of less than 3 mms, typically about 1 mm, and a length to diameter ratio of about 5:1. The
20 nozzle bore in the jewel nozzle has a diameter of 60 micrometres and an l:d ratio of from 2:1 to 3:1 and the orifice at the distal end of the nozzle bore has a diameter of 60 micrometres.

25 Ink is fed under a pressure of 1 bar to an ink gallery 17 encompassing wall 13 and enters the valve head chamber via radial ports 18. When the plunger is in its rest position as shown in Figure 1, the pad 15 is in sealing engagement with the face of the jewel nozzle 12 and thus prevents
30 flow of ink through the nozzle orifice. In order to enhance the seal between the pad 15 and the jewel 12, we

- 53 -

prefer to provide the proximal face of the jewel with one or more raised annular sealing ribs (not shown). This has the surprising effect of reducing the formation of satellite droplets when the valve is operated at high
5 frequencies, typically in excess of 2 kHz.

Such a valve can be operated at frequencies of from under 1 kHz to over 8 kHz to produce consistently sized droplets in the size range 60 to 150 micrometres by controlling the
10 length for which the current flows in the coil 3 and the frequency at which such current pulses are applied to the coil.

As indicated above, the valve is preferably used in an
15 array with other valves to form a multi-nozzle print head which extends transversely to the line of travel of a substrate upon which an image is to be printed. Such an array is shown in Figures 2 and 3. In this case the terminal portion 11 of the housing 10 is provided by a
20 trough-shaped nozzle plate 30 carrying the nozzles 12 and serving as a manifold to form the ink flow gallery 17 feeding ink from ink inlet spigots 31 at each end of the nozzle plate via the inlet ports 18 to the individual valve head chambers 14 of the valves in the array. In a
25 further alternative, the individual valve head chambers 14 are omitted so that ink from the gallery 17 flows directly into a nozzle bore when a plunger is retracted. The array is provided with a connector 32 by which individual electric current supplies can be fed to the coils 3 in
30 each of the valves. In such an array, the housing 4 serves to reduce electrical and magnetic cross talk

- 54 -

between adjacent valves in the array.

Such valves and arrays can be made by machining appropriate metal components. However, one alternative
5 form of construction is to form the tube 2 as a ceramic or silicon member 40 as shown in Figure 5. The coil 41 can be formed in grooves 42 cut in the external surface of the tube 40 so that the radial distance between the coil and the plunger 43 journaled within the tube is reduced. The
10 coil 41 can be a wire coil wound into the grooves 42; or can be a conductive track which is deposited by any suitable means in the grooves 42. If desired, the assembly can then be coated with a polymer to retain and protect the coil within the grooves. In place of a rigid
15 ceramic or silicon support tube, the tube 40 can be provided by a sheet of a flexible support medium, for example a suitable fibre filled polymer or the like, upon which a copper or other conductive track has been formed. The support medium is then rolled into a cylinder to form
20 a cylindrical support carrying the coil upon its inner or outer face. In such designs, the tube 40 can extend axially to form the radial walls 44 of the valve head chamber and the distal open end of the tube closed with a jewel nozzle 45. The whole assembly can then be encased
25 in a stainless steel or other tube 46 which acts to support the assembly and provide the magnetic return path as screening for the coil. The ends of the tube 46 can be inwardly crimped to secure the tube 40, the coil 42 and the jewel 45 in position.

30

In place of the above forms of construction, an assembly

- 55 -

of valves can be formed as shown in Figure 6 by forming a nozzle plate 50 from a silicon or ceramic frit or other material. This plate is provided with jewel nozzles 51 at the desired spacings along the plate 50. Plate 50 is
5 provided with upstanding tubular members 52 which form the tubes 40 of the valve design of Figure 5. The coils 53 are wound or otherwise formed upon the upstanding tubular members 52 and the array is completed as in Figure 5. The valve head chamber 54 is formed by the terminal distal
10 portions of the tubular members and radial ink inlet ports may be provided to enable ink to flow into the valve head chamber. A plunger 55 is journaled in tubular members 52 for axial reciprocation under the influence of coil 53. In place of the jewel nozzle forming the closed distal end
15 to the valve head chamber, the plate 50 can be provided as a continuously extending plate so as to form closed ends to the upstanding tubular members 52. These closed ends can then be pierced, for example by a laser, to form the bores therethrough and the nozzle orifices.

20
In place of the radial ink inlet ports to the valve head chamber 14 or 54, ink can flow axially past the plunger 1 or 55 from an ink inlet to the axially extending passages provided by the space between the tubular members 2 or 52
25 and the plungers 1 or 51. To form the axial passages past the plunger, the bore in tubular member 2 or 52 can have an oval or polygonal cross section and plunger 1 or 55 has a circular cross section. However, it is preferred to form plunger 1 or 55 with axial flats or flutes to it
30 which provide axial passages between the plunger and the circular cross section bore of the tubular member as shown

- 56 -

in Figure 7.

A particularly preferred form of construction of the print head is shown in Figure 8. A foil nozzle plate 100 is
5 formed with a plurality of bores 101 therethrough having a length of 120 micrometres and a diameter of 75 micrometres. The plate is made from stainless steel and the bores are formed either by needle punches or by laser drilling each hole. Alternatively, the bores 101 can be
10 formed by electro-machining, which technique can also be used to form the raised annular ridge 102 around the inlet to each of the bores 101. This foil nozzle plate is clamped between two stainless steel support plates 103 and 104. Plate 104 is formed with a single manifold chamber
15 105 which extends over all the bores 101 formed in plate 100. Alternatively, the chamber 105 can be formed in plate 100.

A valve assembly 110 contained in a support housing 111 is
20 secured to plates 100, 103 and 104 with each of the plungers in a valve mechanism within the assembly in register with a bore 101. The valve mechanisms comprise a coil wound upon a support tube 112 within which a plunger 113 is a loose sliding fit. Each coil is surrounded by a
25 stainless steel housing 114 which is crimped to an apertured support plate 115 clamped between housing 111 and plate 104 to locate and secure each valve mechanism with the plunger projecting through the aperture in register with a bore 101 in the nozzle plate 100. Each
30 plunger 113 is made from a 45/55 Ni/Fe alloy sold under the trade mark Permenorm 5000 and is 1 mm in diameter and

- 57 -

7.5 mms long. The electrical contacts for the coils are fed from a multi-contact plug and socket from a computer controlled power source, not shown. The valve head chamber for each valve mechanism 110 is provided by the
5 single manifold chamber 105 which is fed with ink from each end of plate 104.

As indicated above, the operation of the valve is controlled by a computer 20 in response to a CCD camera or
10 array 21 or other sensors 22 detecting the quality of the printed dots and/or other factors such as temperature, voltage, frequency of operation of the valve which also affect the printed dot quality. Thus, the computer 20 determines which valve to open in the array of Figure 2
15 and for how long so as to print a drop of the desired size at the desired position on the substrate 23 passing the print head 24. At slow frequencies of operation, for example below 1 kHz, this will usually result in a good quality dot being printed on the substrate without the
20 need for the computer to apply any compensation correction to the form of electrical pulse applied to the coil. However, as the frequency increases, say to 2 kHz or more, the quality of the printed dot may suffer, for example due to the sudden closure of the valve causing the formation
25 of satellite dots. The computer can respond to this by detecting from the CCD array that such satellite dots are being formed and causing the shape of the pulse of electric current applied to the coil to change so that the movement of the plunger at each extreme of its travel is
30 reduced. This will reduce the sudden-ness of the closure of the valve by causing the plunger to soft land against

- 58 -

the face of the jewel nozzle or end wall of the valve head chamber. Alternatively, the computer can respond to the instruction to print at high frequencies by reducing the open time of the valve by reference to a look up table 25
5 which carries a list of reductions in open time for a range of operating frequencies. Similarly, the software controlling the operation of the print head can detect when a valve has been idle for any length of time and provide, through another look up table, a signal to
10 increase the open time of the valve for the initial dots printed by that valve to compensate for any drying out of the ink within the valve and/or at the nozzle orifice. In such cases, it is preferred that the information between the computer and the look up table be exchanged as byte
15 sized signals so that up to 256 possible permutations of open time and operating frequency can be accommodated in a single signal.

By way of comparison, when the plunger of the valve
20 mechanism shown in Figure 1 is made from a conventional material having a saturation flux density of about 1.2 Teslar, a coercivity of about 0.95 a/cm and a relative magnetic permeability of about 3,000, the valve cannot be reciprocated at frequencies greater than about 800 Hz,
25 even though it is small and has a low mass. At current pulse frequencies for driving the coil of the valve above this, the plunger remains static within the coil and merely vibrates without significant axial movement. We believe that this is due to the failure of the material of
30 the plunger to be able to respond rapidly enough to the pulses of current and that the plunger remains at

- 59 -

substantially the same magnetic state between the current pulses due to the magnetic hysteresis of the material.

In a further comparison, the valve of Figure 1 was
5 operated with a nozzle bore having a length to diameter ratio of 10:1, 8:1, 5:1, 4:1, 2:1 and 0.5:1 and at a drive current frequency of 2 kHz. At the 10:1 ratio, the pressure required to feed the ink through the bore to achieve a consistent printed dot size was about 10 Bar.
10 However, such a pressure is too high for use with conventional drop on demand print heads and would have resulted in rupture of components. If the pressure was reduced to a more acceptable level, say about 3 Bar, the rate of flow of ink through the print head was
15 insufficient to provide ink to form the droplets consistently so that the printed dots were of uneven size and there were missing dots where the valve had not been able to acquire ink from the reservoir.

20 Where the ratio was 8:1, the pressure required to feed the ink to the nozzle bore to achieve uniform printed dot size and quality was 5 Bar, which is at the upper extreme of operating capability of the components of a drop on demand printer.

25 Where the ratio was 5:1, 4:1 or 3:1, the printer operated successfully at an ink pressure of 1 Bar and could print consistent dots at coil drive current frequencies of from less than 1 kHz to 7 kHz. As the length of the nozzle was
30 reduced the quality of the printed dot improved marginally with the reduction in the l:d ratio. However, when the

- 60 -

1:d ratio was reduced further from 3:1 to 2:1, there was a very much more marked improvement in the response of the valve to start up after a rest period. This improvement could not readily be explained.

5

Where the ratio was 0.5:1, the printer could not be operated, even at ink pressures of 0.1 Bar without causing spraying of the ink and the formation of multiple small dots as well as the desired main dots.

10

The use of a preferred form of drop on demand print head as shown in Figure 8 in printing images on a carpet pile fabric having a pile length of 3 mms under on-line software control will now be described by way of illustration only.

15

The printer shown in Figure 8 is a modification of the print head shown in Figure 2 in which the nozzle plate 100 is formed with a plurality of bores 101 therethrough having a length of 1000 micrometres and a diameter of 500 micrometres. The plate is made from stainless steel and the bores are formed either by needle punches or by laser drilling each hole. Alternatively, the bores 101 can be formed by electro-machining, which technique can also be used to form the raised annular ridge 102 around the inlet to each of the bores 101. This foil nozzle plate is clamped between two stainless steel support plates 103 and 104. Plate 104 is formed with a single manifold chamber 105 which extends over all the bores 101 formed in plate 100. Alternatively, the chamber 105 can be formed in plate 100.

20
25
30

- 61 -

A valve assembly 110 contained in a support housing 111 is secured to plates 100, 103 and 104 with each of the plungers 113 in a valve mechanism within the assembly in register with a bore 101. The valve mechanisms comprise a coil wound upon a support tube 112 within which a plunger 113 is a loose sliding fit. Each coil is surrounded by a stainless steel housing 114 which is crimped to an apertured support plate 115 clamped between housing 111 and plate 104 to locate and secure each valve mechanism with the plunger projecting through the aperture in register with a bore 101 in the nozzle plate 100. The electrical contacts for the coils are fed from a multi-contact plug and socket from a computer controlled power source, not shown. The valve head chamber for each valve mechanism 110 is provided by the single manifold chamber 105 which is fed with ink from each end of plate 104.

The plungers 113 are made from a ferromagnetic alloy having a saturation flux density of 1.6 Teslar, a coercivity of 0.2 a/cm and a relative magnetic permeability of 100,000. The alloy is a 45/55 Ni/Fe alloy sold under the trade mark Permenorm 5000 and each plunger is 2 mm in diameter and 7.5 mms long. The nozzle bore 101 and its distal orifice have a diameter of 300 micrometres and the bore has an l:d ratio of from 2:1 to 3:1.

Ink is fed under a pressure of 1.5 Bar from a reservoir (not shown) to the manifold chamber 105 and enters the bore 101 when the plunger 113 is retracted by applying current to coil 112. Where different coloured inks are to

- 62 -

be applied, each coloured ink may be held in a separate reservoir, each feeding ink to a separate print head.

Such a valve can be operated at frequencies of from under
5 1 kHz to over 8 kHz to produce consistently sized droplets
in the size range 250 to 500 micrometres by controlling
the length for which the current flows in the coil 112 and
the frequency at which such current pulses are applied to
the coil.

10

The print head of Figure 8 was used to apply inks having a
viscosity of 300 Cps through a nozzle bore and orifice of
500 micrometres diameter to apply different coloured inks
to the pile of a neutral wool fibre coloured tufted
15 carpet. The print head was operated at a frequency of 2
kHz to achieve substantially uniform coloration of the
individual fibres within the pile. The boundaries between
different colours of the printed image were clearly
defined and the definition of the image was excellent. In
20 an alternative operation, the computer was programmed not
print an ink dot at the boundary between two colours so as
to minimise the risk of colour bleeding between areas of
different colours.

25 The calibration of a solenoid valve using software will
now be described with respect to Figures 9 to 13

Figure 9 shows a schematic depiction of a solenoid valve
10 which is suitable for use with this aspect of the
present invention. The valve 910 comprises plunger 920,
30 tube 930 and coils 940. The plunger 920 comprises a

- 63 -

ferromagnetic material (or any other magnetic material) and is received within the tube 930 so as to be able to move reciprocate freely axially within the tube. The plunger can be impelled, for example towards the open end
5 of the tube, by the application of a current to the coils 940, the current generating a magnetic field within the tube, which causes a magneto motive force to act upon the plunger. The timing and frequency of the current pulses applied to the coils can be controlled by a computer (not
10 shown). The solenoid valve additionally comprises a return mechanism (not shown), such as a spring, that acts to return the plunger to its initial position once the plunger has completed its full range of travel. In a preferred aspect, the solenoid valve is one as shown and
15 described with reference to Figures 2 or 8 above.

In practice, a print head will comprise an array of such valves that are arranged in a square or rectangular arrangement. Figure 10 shows two exemplary valves 210a,
20 210b from such a print head matrix 220. Associated with each valve is valve control means 215a, 215b, each of the valve control means being in communication with a central computer system 230. The operation of each valve is controlled by the transmission of control pulses from the
25 central computer system 230 to each of the valve control means 215a, 215b. The valve control means are responsive to the central computer system such that the central computer system is able to vary the time that the valves are held open for. This controlled variation of the valve
30 enables ink drops of a desired size to be produced for depositing upon the substrate 250. Preferably, the print

- 64 -

heads are as shown in and as described with reference to Figures 2 and 8 above.

The print head can be calibrated upon manufacture and then
5 at periodic intervals during its operation. The central computer system instructs the print head to generate a predetermined matrix of drops. This test matrix is deposited on a test substrate and the printed image can be examined to determine the correlation of the printed image
10 to the original test matrix. If the ratio of the size of a printed pixel to the size of the respective pixel of the original test matrix is outside a threshold value, then the respective valve control means can be instructed to change the time that the valve is to be opened for. If
15 the printed pixel is too small, then the valve open time will be increased (either by the addition of more time or by multiplying the valve open time by a suitable constant). Similarly, if the printed pixel is too large, then the valve open time will be decreased accordingly.
20 The threshold that is used to determine whether a printed pixel is too small or too large may be varied in accordance with the nature of the print substrate and/or the application that the print head is being used for.

25 As variations in printed pixel size will depend upon mechanical variations within the valve, it is possible that a valve may operate satisfactorily for one size of pixel or within a given range of valve operating rates. Therefore, the calibration may need to be repeated across
30 the range of pixel sizes and valve rates that will be used by the valve. The range of calibration factors that are

- 65 -

required by each valve may be stored in a look-up table,
or it may be possible to determine one or more equations
such that the relevant calibration factor can be
calculated given the desired valve operation rate and
5 pixel size.

In an alternative embodiment, imaging means 240 may be
additionally coupled to the computer control system and
aligned so as to view the area of the substrate that the
10 print head matrix prints upon. When a test matrix is
printed upon the substrate, the image means is able to
convert that image to an electrical signal that can be
transmitted to the central computer system. The central
computer system can, after any necessary image processing
15 (digitising, filtering, etc.), compare the printed image
with the original test matrix that is stored within the
central computer system. The ratio of pixel sizes can be
determined for each pixel and calibration factors
calculated for each valve as required. The central
20 computer system can then communicate the calibration
factors to the valve control means associated with the
valves that require calibration.

The valve control means receives, interprets and executes
25 signals that are received from the central computer
system. It will be readily understood that the valve
control means may be implemented such that each valve has
a dedicated control means or alternatively that a number
of valves may be controlled by a single control means.

30

- 66 -

In a preferred embodiment, the valve control means comprise a field programmable gate array (FPGA). FPGAs comprise memory and logic elements that can be configured by the user to provide a desired functionality.

5

In the preferred embodiment, the FPGA, and associated devices, is used to control a linear array of 16 valves. Referring to Figure 11, the valves 610a, 610b, ..., 610p are controlled by valve control means that comprise FPGA 616, electrically erasable programmable ROM (EEPROM) 617, RAM 618, programmable ROM (PROM) 619 and input/outputs 622, 624, 626. The FPGA 616 is connected to each of the valves 610a, 610b, ..., 610p, EEPROM 617, RAM 618 & PROM 619. All three input/outputs 622, 624, 626 interface with the FPGA.

15 When the FPGA is powered up, it loads its internal configuration data from PROM 619 and then follows the sequences that have been loaded from the PROM. The EEPROM 617 stores a range of data comprising a look-up table comprising data associated with each of the valves, data specific to the valve control means and FPGA, status information, etc. The FPGA will load this data from the EEPROM and then initialise the RAM 618, by writing zero values into each memory location in RAM. The FPGA will then wait to receive print data or other commands from one

25 of the inputs. Input/output 622 is connected to the computer control system and input/output 624 can be used to connect to a further valve control means (see below). Input 626 provides a series of pulses that are used in co-ordinating the printing process. When the array of valves

30 is printing onto a substrate, the substrate is normally moved underneath the nozzles related to the valves. The

- 67 -

series of pulses supplied to input 626 may be generated from an encoder applied to a shaft in the apparatus that is moving the substrate relative to the valves.

5 Figure 12 shows a schematic depiction of a number of registers that are formed with the FPGA when the FPGA configuration data is loaded from PROM 619. The first register 631 is used to write to and read from the EEPROM 617 and is also used when initialisation data is read from
10 the EEPROM. Second register 632 receives print data from the computer control system, such as the alphanumeric characters or bitmaps to be printed, or a signal to initiate a printing process. Second register 632 also writes print data to the RAM and is used to initialise the
15 RAM during the start-up phase. The third register receives configuration data from the computer control system, such as data controlling the slant that may be applied to the print head. Fourth register 634 receives print data from the RAM and passes it to the fifth
20 register 635, which uses the print data to operate the valves 610.

A desired print image (which may include alphanumeric characters) is entered into the computer control system
25 and this image is then converted into raster data that is to be communicated with the valve control means. The valves 610 may be operated for different periods of time so as to provide the appearance of 16-level greyscale images. Thus the print data can be supplied in the form
30 of a raster comprising a 4 bit word for each valve, with the value of the 4-bit word determining the greyscale that

- 68 -

is to be generated by the valves. The print data is received by the second register and written into the RAM 618. The RAM is logically arranged in 16 rows, with each of the valves corresponding to a row. There is a plurality of columns, each of which corresponds to a time slot. Each raster scan also corresponds to a time slot and the time slot is determined by the frequency at which the shaft encoder supplies pulses to the FPGA.

10 When print data is received at the FPGA, the second register interprets the greyscale data for each valve, obtaining the time that each valve must be opened for in order to generate the desired greyscale from a look-up table held in the first register. In theory, each valve should be held open for the same period of time in order to generate the same greyscale, but mechanical variations in each valve will lead to each valve having slightly different characteristics. Calibration factors that account for these differences are held in the look-up table. The valve times are then written into the RAM, using as many columns as are necessary to store all of the rasters. A write pointer is set to the first column of the data. Each memory location holds the grey scale value for the associated valve and time slot.

25

When the next shaft encoder pulse is received the RAM column indicated by the write pointer is read to see which of the 16 valves need to be operated, i.e. which memory locations have non-zero entries. Once the memory locations have been read then all the memory locations in the column are overwritten with zero.

30

- 69 -

The identity of these valves, along with the time for which the valves are to be held open are then transmitted to the fourth register, which may perform further operations on the valve open times in order to correct for valve operation at high speed or a long rest period between subsequent operations of the valve. The valve open times are then passed to the fifth register which calculates the number of shaft encoder pulses that are equivalent to the valve times. The valves are then opened for a period of time equal to that number of shaft encoder pulses.

As the valves 610 are electro-mechanical devices, their size provides a limitation to the print resolution that can be obtained. Typically, each valve may be provided at an offset of 4mm from the adjacent valve(s). If a greater resolution (i.e. smaller pixel separation is required) then the array may be slanted so that the valves are closer together in one axis. The disadvantage of this is that if no correction is made to the print rasters then the desired image will be printed out slanted.

A correction to compensate for the slant of the print head may advantageously be provided using the RAM to provide a slant to the print raster data. Once the greyscale data has been translated into valve open times, rather than writing the valve data into a vertical column, the write data can be offset across a number of columns. For example, if the desired slant angle is 45° then the valve open time for the first valve should be written into the

- 70 -

column indicated by the write pointer, the valve open time for the second valve should be written into the next column along from the column indicated by the write pointer, and so on, such that the valve open time is
5 written into the RAM at the desired slant angle.

Typically the 16-level greyscale can be provided using valve open times between approximately 80 μ s and 250 μ s. It has been found advantageous to initially open the valve by
10 providing a first voltage for a first period of time and to provide a second voltage that is lower than the first voltage, for a further period of time in order to hold the valve open. This reduces the possibility that the valve remains open for longer than is required to provide the
15 desired greyscale, leading to decreased printing performance and also enables the valve to be held in the open position for long periods without reduced risk of over-heating. It has been found particularly advantageous to apply a 36V pulse for approximately 80 μ s and a second
20 pulse of approximately 5V for the remainder of the time that the valve remains open.

In a further preferred embodiment, the valve control means and valves described above with reference to Figure 11
25 will be co-located upon a single circuit board 650. A number of circuit boards can then be connected in serial and physically located in a vertical array so that the valves can deposit a two-dimensional matrix on a print substrate. In such a case (see Figure 14), one of the
30 boards 650a will be connected via serial input/output 622 to the computer control system 230 and to the second board

- 71 -

via serial input/output 624. The second board 650b will be connected to the first board via serial input/output 622 and to the third board 650c via serial input/output 624, and so on. The last board in the serial chain can
5 detect its position as its serial input/output 624 will have no connection. On power up, the last board in the serial chain assigns itself address 0 and transmits this address to the preceding board, which then assigns itself address 1. This process continues, with the address value
10 being incremented until each board has an assigned address. The first board 650a will then report its address to the computer control system such that the system is aware of the number of connected boards. The system will prefix any communication to a board with that
15 board's address. Preferably 16 boards are connected together to provide a 16 x 16 printing matrix.

The FPGA used in the preferred embodiment was a Xilinx Spartan II XC2S100 which was preferred as its
20 configuration was determined by the data loaded from the PROM in start up. Such an FPGA may be replaced by a cheaper device in which the FPGA is hardwired, for example by blowing fuses to form logic elements, rather than configurable through software.

25

It will be understood that the above technique for calibrating a solenoid valve is suitable for use with any type of solenoid valve and in any application in which solenoid valves are used. However, the technique is of
30 especial application to the compact high speed valves of the invention where the small size of the components makes

- 72 -

manual adjustment of the position of pole pieces and other components difficult and inaccurate.

As stated above, the software and computer control can be
5 used to decelerate the movement of the plunger at either
or both extremes of its travel so as to reduce spattering
of the ink from the nozzle orifice due to excessive
slamming of the plunger against its seat.

10 According to another aspect of the present invention there
is provided a method of operating a solenoid valve, the
method comprising the step of energising an electric coil
to generate a magnetic field in order to reciprocally
drive a plunger within a coil, characterised in that the
15 magnetic field is controlled such that the speed of the
plunger is decreased as the plunger approaches at least
one of its extremes of movement. The control of the
magnetic field may be achieved in a number of ways.

20 In a preferred embodiment, the magnetic field may be
controlled such that the speed of the plunger is decreased
as the plunger approaches its closed position, in order to
reduce the impact as the valve closes. The magnetic field
may be controlled such that the speed of the plunger is
25 decreased, the magnetic field resisting a force exerted on
the plunger by a return means. Such a method of operating
the valve is now described with reference to Figures 14 to
16.

30 Figure 14 shows a schematic depiction of a solenoid valve
710 which is suitable for use with this method of

- 73 -

operating the valve. The valve 710 comprises plunger 720, tube 730 and coils 740. The plunger 720 comprises a ferromagnetic material (or any other magnetic material) and is received within the tube 730 so as to be able to move freely along the axis of the tube. The plunger can be impelled, for example towards the open end of the tube, by the application of a current to the coils 740, the current generating a magnetic field within the tube, which causes a magneto motive force to act upon the plunger.

10 The timing and frequency of the current pulses applied to the coils can be controlled by computer (not shown). The solenoid valve additionally comprises a return mechanism (not shown), such as a spring, that acts to return the plunger to its initial position once the plunger has

15 completed its full range of travel.

Conventionally, current is supplied to energise the coils as a simple square wave (or as a triangular wave having a steep gradient) in order to provide a rapid acceleration of the plunger towards the closed end of the tube.

20 Similarly, once the plunger has reached its maximum travel within the tube, the current is reduced quickly in order to reduce the magnetic force acting on the plunger quickly. This is advantageous as any magnetic force will

25 oppose the force exerted upon the plunger by the return mechanism and thus the greater the magnetic force, the slower the return time of the plunger.

However, we have found that in some high-speed applications for solenoid valves, such as their use within

30 ink jet printers, and notably within 'drop on demand' ink

- 74 -

jet printers, the increased rate at which magnetic forces are applied to and removed from the plunger cause the formation of satellite droplets in addition to the desirable main droplets. We have found that this is
5 caused by the sudden deceleration of the valve plunger as it reaches the valve closed position at the end of its travel.

Figure 15 shows a schematic depiction of a solenoid valve
10 710 which is used within a drop on demand inkjet printer. The design and construction of the valve and the print head is substantially identical to that shown in Figure 9 as described above. The plunger 720 is, in the valve closed position as shown in Figure 15, received upon the
15 inlet end of a nozzle bore 750 so as to shut off the flow of ink to that nozzle bore. The tube 730 extends at its open end to form a valve head chamber 760 which is provided with an inlet 770 through which ink can be supplied to the chamber. Energising the coil 740 through
20 the application of an electrical current to the coil impels the plunger along the tube, towards the closed end of the tube. The movement of the plunger unseals the end of the nozzle bore, allowing ink to flow through the nozzle orifice. Once the magneto motive force (MMF) is
25 removed from the plunger (through the removal of the current from the coils 740) the return mechanism (not shown) returns the plunger to its closed position such that the plunger acts to seal the nozzle bore. Some form of seal or baffle may be applied to the nozzle bore and/or
30 the end face of the plunger in order to enhance the seal between the plunger and the nozzle bore so as to reduce

- 75 -

the probability of ink entering the nozzle bore when the plunger is in its rest position.

It is desirable for the return mechanism to return the
5 plunger to its closed position quickly to avoid the nozzle
being left open for too long: thus it is important to turn
off the current pulse to the coils 740 as soon as
possible. The reciprocating motion of the plunger within
the tube and the chamber is controlled so that a precisely
10 controlled drop of ink will be ejected from the nozzle
orifice to be deposited upon a substrate (not shown).
When the valve is operated at high frequencies, typically
from 2 to 4 kHz, this can cause problems due to the method
by which the coils are energised.

15

The energising of the coils causes the plunger to undergo
a rapid acceleration until its motion is impeded by the
end of the tube. Only the damping effect of the fluid
within the tube and the force exerted by the return
20 mechanism opposes the motion of the plunger caused by the
energising of the coils.

The abrupt nature of the plunger's motion causes the
formation of satellite droplets around the intended drops
25 that are printed on the substrate. It is believed that
the rapid acceleration of the plunger as it moves away
from its rest position is responsible for the formation of
these satellite droplets and that the problem is
exacerbated due to the limited fluid damping provided by
30 the fluid within the tube. Furthermore it has been
observed that, if the force exerted upon the plunger by

- 76 -

the return means is too great and if the magnetic force applied to the plunger is minimal as the plunger returns to its rest position, then the impact of the plunger on the inlet to the nozzle bore can cause damage to the structure of the plunger or the nozzle (or to any sealing means provide on the nozzle or the plunger).

The possibility of producing such satellite droplets can be reduced by altering the method by which the plunger is impelled. Rather than using a square (or triangular) current pulse to energise the coils as described above, the current is applied to the coils in a more gradual fashion. Similarly, if the manner in which the coils are de-energised is controlled appropriately, then the deceleration of the plunger will be less abrupt, which should serve to further reduce problems which are caused by the impact of the plunger on the nozzle bore inlet. It is believed that similar problems may occur when solenoid valves are operated at very high speeds in applications other than ink jet printing.

The current may be applied as a generally triangular pulse (which may or may not be symmetrical in the time domain), as a generally Gaussian pulse, a generally sinusoidal pulse or some other form of non-square pulse that reduces the initial acceleration and final deceleration of the plunger. The exact nature of the solenoid valve and the rate at which it is being opened will determine whether or not the abrupt acceleration and deceleration of the plunger has a deleterious effect upon the operation of the solenoid valve.

- 77 -

Figure 16a shows a graphical indication of a typical triangular wave that is conventionally used to energise the coils. Figure 16b shows a graphical indication of a triangular wave that is used according to the method of the present invention to energise the coils. It can be seen that in the first part of the waveform shown in Figure 16b the gradient of the wave is less than for the waveform of Figure 16a. This ensures that the plunger is accelerated away from its rest position at a slower initial rate, reducing the possibility of forming satellite droplets. It will also be noticed that in the latter part of the waveform there is a greater current so that the magnetic force exerted upon the plunger acts to damp the motion of the plunger, moderating the effect of the return mechanism. It will be understood that the exact waveform will be dependent upon, amongst other factors, the nature and structure of the solenoid valve, the speed at which it is operated, the application in which it is used, etc., and that the waveform shown in Figure 16b is purely exemplary.

Experimentation can be used to determine a suitable, or optimum, waveform or set of waveforms for use with a particular application. One waveform that was found to be of advantage is shown in Figure 16c. It has been found advantageous to initially open the valve by providing a first voltage for a first period of time and to provide a second voltage that is lower than the first voltage, for a further period of time in order to hold the valve open. This reduces the possibility that the valve remains open

- 78 -

for longer than is required to provide the desired greyscale, leading to decreased printing performance. It has been found particularly advantageous to apply a 36V pulse for approximately 80 μ s and a second pulse of
5 approximately 5V for the remainder of the time that the valve remains open.

During the high speed operation of solenoid valves in ink jet printing, the ink drops being deposited on a substrate
10 can be monitored using a CCD (charge coupled device) camera coupled to a computer control system to determine the number of problem satellite droplets that are being formed and the frequency with which they are being formed. The collected data can be analysed by the computer, which
15 can vary the current pulses accordingly to reduce the number of satellite droplets being formed. The computer may select a current pulse from a range of pulses stored in memory, along with an indication of the likelihood of a given current pulse reducing the formation of satellite
20 droplets.

In a preferred embodiment, the valve control means comprise a field programmable gate array (FPGA) using the circuitry shown in Figure 12. FPGAs comprise memory and
25 logic elements that can be configured by the user to provide a desired functionality.

The invention has been described above in terms of a print head incorporating a solenoid valve of the invention.
30 However, it will be appreciated that the use of software to calibrate, operate and control the movement of the

- 79 -

plunger in response to signals from one or more sensors can also be applied to other forms of solenoid valve.

Accordingly, from another aspect, the invention provides a
5 drop on demand printer in which a droplet of ink or other
fluid is ejected from a nozzle orifice to form a printer
dot upon a substrate and in which the flow of the fluid
from a source of the fluid to the nozzle orifice is
regulated by a valve mechanism comprising a plunger member
10 adapted to be reciprocated within a coil under the
influence of an electric current applied to the coil,
characterised in that the printer is provided in operative
combination therewith with a computer adapted to control
the operation of the printer, characterised in that:

- 15 a. the computer is adapted to operate in
combination with a mechanism for observing the
ejected droplet and/or the printed dot of fluid
applied to a substrate;
- b. the computer is programmed to detect differences
20 between the observed droplet and/or dot and the
desired droplet and/or dot and to apply a
correction to the current applied to the coil of
the valve regulating the flow of fluid to the
nozzle orifice so as to maintain the desired
25 observed droplet or dot parameters.

Preferably, the computer is provided with one or more look
up tables or other memory means which contain the desired
parameters for the ejected droplet and or/printed dot and
30 the corrections which need to be applied to the operation
of the valve to compensate for deviations from the desired

- 80 -

parameter values. Typically, the parameters being observed are the size, the shape, for example the circularity of the printed dot and the presence of satellite droplets or dots. The memory means may also provide compensations in response to signals from sensors, for example to compensate for temperature and/or voltage changes, to rests periods between operations of the valve and to changes in the frequency of operation of the valve. The computer may vary such operations of the valve as the frequency of operation, the open time of the valve and the shape of the current pulse applied to the coil. As described above, the operation of the valve may be under the control of a time delay means, such as an FAPG, which may be itself controlled by the computer.

15

The invention has been described above in terms of a plunger which has a unitary construction, that is formed as a single component. However, it will be appreciated that where the material of construction has the preferred magnetic properties, it may be possible to generate sufficient magnetic force upon the plunger where part of the plunger is formed as a separate component mechanically connected to the remainder of the plunger and this part is made from a material which has a Tesla value of less than 1.6. Accordingly the present invention also provides a valve of the invention and a print head incorporating such a valve, characterised in that the plunger has a composite construction and at least a major portion thereof is made from a material having a saturation flux density of at least 1.6 Tesla.
